Cryo-electron microscopy (cryo-EM) is an leading technology for single particle reconstruction (SPR) of macro-molecules. *[revise first sentence]* In a cryo-EM experiment, biological samples are rapidly frozen in a thin layer of vitreous ice. The microscope produces a 2-D tomographic image of the samples embedded in the ice, called a *micrograph*. Each micrograph contains tomographic projections of the samples at unknown locations and under unknown viewing directions. The goal is to construct 3-D models of the molecules from the micrographs.

The signal to noise ratio (SNR) of the projections in the micrographs is a function of two dominating factors. On the one hand, the SNR is a function of the electron dose. To keep radiation damage within acceptable bounds, the dose must be kept low, which leads to high noise levels. On the other hand, the SNR is a function of the molecule size. The smaller the molecules, the fewer detected electrons carry information about them. *[This isn't quite accurate: it's about the density of particles in the image; but we want to make a point about size; how do we reconcile this?]*

All contemporary methods in the field split the reconstruction procedure into several stages. The first stage consists in extracting the various particle projections from the micrographs. This stage is called *particle picking*. Later stages aim to construct a 3-D model of the molecule from these projections. The quality of the reconstruction eventually hinges on the quality of the particle picking stage. Figure 1 illustrates how particle picking becomes increasingly challenging as the SNR degrades.

Crucially, it can be shown that reliable detection of individual particles is impossible below a certain critical SNR. This fact has been recognized early on by the cryo-EM community. In particular, in an influential paper from 1995, Richard Henderson (1) investigates the following questions:

For the purposes of this review, I would like to ask the question: what is the smallest size of free-standing molecule whose structure can in principle be determined by phase-contrast electron microscopy? Given what has already been demonstrated in published work, this reduces to the question: what is the smallest size of molecule for which it is possible to determine from images of unstained molecules the five parameters needed to define accurately its orientation (three

parameters) and position (two parameters) so that averaging can be performed?

In that paper and in others that followed (e.g., (2)), it was established that particle picking is impossible for molecules below a certain weight (below ~50 kDa). Joachim Frank voices a similar observation in his 2017 Nobel prize lecture: “*Using the ribosome as an example, it became clear from the formula we obtained that the single-particle approach to structure research was indeed feasible for molecules of sufficient size: Particle Size > 3/[Contrast² × Resolution (as length) × Critical Electron Dose]*” (3). *[As these two leaders of the cryo-EM community point out,]* it is impossible to reconstruct small molecules by any of the existing computational pipelines for single particle analysis in cryo-EM, because the particles themselves cannot be picked from the micrographs.

The unique issues raised by small particles have been mitigated by recent technological advances in the field, including the use of Volta phase plates (4, 5) and scaffolding cages (6). Despite this progress, detecting small molecules in the micrographs remains a challenge. We note that nuclear magnetic resonance (NMR) spectroscopy and X-ray crystallography are well suited to reconstruct small molecules. Yet, cryo-EM has a lot to offer even for molecules with already known structures obtained via NMR spectroscopy or X-ray crystallography, because these methods have limited ability to distinguish conformational variability. *[Need a ref for this claim.]*

In this paper, we argue that there is a gap between the two questions in Henderson’s quoted excerpt above, and that one may be able to exploit it to design better reconstruction algorithms. Specifically, the impossibility of particle picking does not necessarily imply impossibility of particle reconstruction. Indeed, the aim is only to reconstruct the molecule: estimating the locations of the particles in the micrograph is merely a helpful intermediate stage when it can be done. Our main message is that the limits particle picking imposes

Significance Statement

Authors must submit a 120-word maximum statement about the significance of their research paper written at a level understandable to an undergraduate educated scientist outside their field of speciality. The primary goal of the Significance Statement is to explain the relevance of the work in broad context to a broad readership. The Significance Statement appears in the paper itself and is required for all research papers.

Please provide details of author contributions here.

Please declare any conflict of interest here.

on molecule size do not necessarily translate into limits on particle reconstruction.

As a proof of concept, we study [This sentence beginning makes it sound like what follows is our main point; should the main point be the 3D recovery, even if low-res?] a toy model for which it is easier to convey the mathematical principles. In this toy model, an unknown image appears multiple times at unknown locations in each of several micrographs, each affected by additive Gaussian noise—see Figure 1 for an illustration. The goal is to estimate the planted image. The task is challenging in particular when the SNR is low enough that particle picking (identifying the locations of each image in each micrograph) cannot be done reliably. This problem is interesting of its own as it appears in other scientific applications, including spike sorting (7), passive radar (8) and system identification (9).

In order to recover the image, we use autocorrelation analysis. Specifically, we relate the autocorrelations of the micrographs to the autocorrelations of the image. For any noise level, these autocorrelations can be estimated to any desired accuracy, provided that we observe sufficiently many image occurrences and the latter are separated in the micrograph. Importantly, there is no need to detect individual image occurrences. The autocorrelations of the micrographs are straightforward to compute and require only one pass over the data. After estimation of the density of particles in the micrographs, these directly yield estimates for the autocorrelations of the target image itself. To estimate the image itself from its estimated autocorrelations, we solve a nonlinear inverse problem.

Beyond this 2-D proof of concept, we look toward 3-D reconstruction as well. Zvi Kam (10) first proposed autocorrelation analysis for 3-D reconstruction, under the assumption of perfect particle picking: his method used autocorrelations of the picked particles. In contrast, we derive the mathematical relation between the autocorrelations of the micrographs as a whole and the 3-D volume, under some simplifying conditions. We show a few numerical examples and outline the future developments required to make this method applicable on real data. [This paragraph will be changed according to the final results we will show]

Another interesting feature of the described approach pertains to model bias, whose importance in cryo-EM was stressed by a number of authors (11–14). In the classical “Einstein from noise” experiment, multiple realizations of pure noise are aligned to a picture of Einstein using template matching and then averaged. In (11), it was shown that the averaged noise rapidly becomes remarkably similar to the Einstein template. In the context of cryo-EM, this experiment exemplifies how prior assumptions about the particles may influence the reconstructed structure. This model bias is common to all particle picking methods based on template matching. In our approach, no templates or human intervention are required, thus significantly reducing concerns about model bias.

[Need to cite (15). Discusses cryo-em for drug discovery and mentions small molecule]

1. Proof of concept: A mathematical toy model

In this section, we present a toy model in order to introduce the mathematical principles enabling estimation of a signal in a low SNR regime, even when detection is impossible. Later, we discuss how these principles carry through for the SPR

problem. We first formulate the model for 1-D signals to ease exposition.

Let $x \in \mathbb{R}^L$ be the target signal and let $y \in \mathbb{R}^N$ be the observed data, where N is assumed far larger than L . Let $s \in \{0, 1\}^{N-L+1}$ be a binary signal indicating (with 1’s) the starting positions of all occurrences of x in y , so that, with additive white Gaussian noise:

$$y = x * s + \varepsilon, \quad \varepsilon \sim \mathcal{N}(0, \sigma^2 I_N), \quad [1]$$

where $*$ denotes linear convolution. While both x and s are unknown, the goal is only to estimate x from y (this is a key difference with other works on sparse blind deconvolution, e.g. (16)). The parameters of the signal s (the locations of its nonzero values) are the *nuisance variables* of the problem. As will be shown next, in a low SNR environment, estimating s is impossible, whereas estimating x is tractable under some conditions on s .

We assume that the binary signals s obey the following *separation condition*: If $s[i] = 1$ and $s[j] = 1$ for $i \neq j$, then $|i - j| \geq 2L - 1$. In words: the starting positions of any two occurrences must be separated by at least $2L - 1$ positions, so that their end points are necessarily separated by at least $L - 1$ signal-free entries in the micrograph.

Our problem can be interpreted as a special case of the *system identification* problem. Similarly to Eq. (1), the forward model takes the form $y = x * w + \varepsilon$, where x is the unknown signal (the system’s impulse response), w is an unknown (often random) input sequence, and ε is an additive noise. The goal of this problem is to estimate x , usually referred to as “identifying the system.” The question of identifiability of x under this observation model is addressed for certain Gaussian and non-Gaussian w in (17, 18). In the special case where w is binary and satisfies our separation condition, we recover our model. The same observation model is used for *blind deconvolution*, a longstanding problem arising in a variety of engineering and scientific applications such as astronomy, communication, image deblurring, system identification and optics; see (19–22), just to name a few.

Likelihood-based methods estimate x as the maximizer of some function $f(x|y)$, where f is derived from the likelihood function of x given the observed signal y . If some prior is assumed on x , then $f(x|y)$ can be taken to be the posterior distribution of x given the data; this is the simplest form of Bayesian inference. Methods based on such formulations are popular nowadays in cryo-EM; see for instance (23, 24). Optimizing the function $f(x|y)$ exactly is often intractable, and thus heuristic methods are used instead. One proposed technique is to use Markov Chain Monte Carlo (MCMC) (25). In special cases, including the case where w is binary, expectation maximization (EM) has been used (25). The EM method for discrete w is based on a certain “forward-backward” procedure used in hidden Markov models (26). However, the complexity of this procedure is superlinear in N , and therefore its usage is limited for big data sets.

Because likelihood methods are computationally expensive, methods based on recovery from moments have also been previously used for system identification. Methods based on the third- and fourth-order moments are described and analyzed in (27–29). Building on such ideas, in the next section we present an autocorrelation analysis for Eq. (1) and study it in Section 3.

Fig. 1. Example of micrographs of size 250×250 with additive white Gaussian noise of variance σ^2 for increasing values of σ . Each micrograph contains the same four occurrences of a 50×50 image of Einstein. In panel (c), the noise level is such that it is very challenging to locate the occurrences of the planted image. In fact, it can be shown that at low SNR, reliable detection of individual image occurrences is impossible, even if the true image is known. By analogy to cryo-EM, this depicts a scenario where particle picking cannot be done.

2. Autocorrelation analysis

In general, for a signal z of length m , the autocorrelation of order $q = 1, 2, \dots$ is given for any integer shifts $\ell_1, \dots, \ell_{q-1}$ by

$$a_z^q[\ell_1, \dots, \ell_{q-1}] = \frac{1}{m} \sum_{i=-\infty}^{+\infty} z[i]z[i + \ell_1] \cdots z[i + \ell_{q-1}], \quad [2]$$

where indexing of z out of the range $0, \dots, m-1$ is zero-padded. For our purposes, this will be applied both to x (of length L) and to y (of length N). Explicitly, the first-, second- and third-order autocorrelations are given by [we may want to remove these explicit formulas]

$$\begin{aligned} a_z^1 &= \frac{1}{m} \sum_{i=0}^{m-1} z[i], \\ a_z^2[\ell] &= \frac{1}{m} \sum_{i=\max\{0, -\ell\}}^{m-1+\min\{0, -\ell\}} z[i]z[i + \ell], \\ a_z^3[\ell_1, \ell_2] &= \frac{1}{m} \sum_{i=\max\{0, -\ell_1, -\ell_2\}}^{m-1+\min\{0, -\ell_1, -\ell_2\}} z[i]z[i + \ell_1]z[i + \ell_2]. \end{aligned} \quad [3]$$

The autocorrelation functions have symmetries. Specifically, $a_z^2[\ell] = a_z^2[-\ell]$, and $a_z^3[\ell_1, \ell_2] = a_z^3[\ell_2, \ell_1] = a_z^3[-\ell_1, \ell_2 - \ell_1]$.

Under the separation condition, the relation between autocorrelations of the micrograph and those of x is particularly simple, as we now show. It is useful to introduce some notation: let M denote the number of occurrences of x in y (that is, the number of 1's in s), and let

$$\gamma = \frac{ML}{N} \quad [4]$$

denote the density of x in y (that is, the fraction of entries of y occupied by occurrences of x .) The separation condition imposes $\gamma \leq \frac{L}{2L-1} \approx 1/2$.

Under the separation condition on s , for shifts in $0, \dots, L-1$, the autocorrelation functions of y depend only on the corresponding autocorrelations of x and the parameter γ . In particular, for the first-order autocorrelation (that is, the mean), since the noise is independent of the signal, the mathematical expectation of a_y^1 is easily seen to be:

$$\mathbb{E}\{a_y^1\} = \gamma a_x^1.$$

(The randomness is over the Gaussian noise ε ; s may be deterministic: under the conditions, the quantity under consideration depends on s only through γ .) We consider the asymptotic regime where $M, N \rightarrow \infty$, while γ remains constant (we see an increasingly large micrograph, containing increasingly many signal occurrences, with constant signal density.) In that regime, the law of large numbers can be used to show the following statement:

$$\lim_{N \rightarrow \infty} a_y^1 = \gamma a_x^1. \quad [5]$$

Thus, given enough data, if γ is known, we can estimate a_x^1 from y . (We show later how to estimate γ as well.) We have a similar observation for the second-order autocorrelation: $a_y^2[\ell]$ computes the correlation between y and a copy of y shifted by ℓ entries. Considering ℓ only in the range $0, \dots, L-1$, one can see that any given occurrence of x in y is only ever correlated with itself (with the same shift ℓ), and never with another occurrence. As a result,

$$\lim_{N \rightarrow \infty} a_y^2[\ell] = \gamma a_x^2[\ell] + \sigma^2 \delta[\ell] \quad [6]$$

for $\ell = 0, \dots, L-1$, where δ denotes the Kronecker delta function. The last part captures the autocorrelation of the noise. Notice that, even if σ is unknown, entries $\ell = 1, \dots, L-1$ still provide useful information about a_x^2 . Along the same lines, one can establish a relation for third-order autocorrelations:

$$\begin{aligned} \lim_{N \rightarrow \infty} a_y^3[\ell_1, \ell_2] &= \gamma a_x^3[\ell_1, \ell_2] \\ &+ \sigma^2 \gamma a_x^1 \cdot (\delta[\ell_1, 0] + \delta[0, \ell_2] + \delta[\ell_1, \ell_2]), \end{aligned} \quad [7]$$

for $\ell_1, \ell_2 = 0, \dots, L-1$. Here too, few entries are affected by σ in the limit. Detailed derivations for identities in this and the next part are given in Appendix B.

[Nico: At this point in the paper, the reader will want to here about recovering x from its moments. That's not what happens: the next section is called theory (a bit too vague); it discusses two things: one is the impossibility of getting s , another is whether we can get x, γ, σ . I propose to split that section in two, and to lead with the recovery part (which is interesting to more people, I expect.)]

3. Theory

If x is known, then the support signal s can be estimated via linear programming in the high SNR regime (30–33). However, in the low SNR regime—even if x is known—estimating the binary sparse signal s is impossible. To prove this argument, we consider an even easier problem, in which someone hands us intervals of length L that either contain the full signal plus noise, or contain just noise, and we are asked to determine which intervals contain signal. Let us assume too that we know the signal x , that we know the probability q that one of the intervals contains a signal, and that we know the noise variance σ^2 . Since we have the full generative model, we can always generate more data as needed; therefore it is enough to consider the hardness of deciding whether a single interval contains signal or not.

Let us abstract this problem. We have two known vectors θ_0 and θ_1 in \mathbb{R}^L . There is a random variable η taking values 0 or 1 with probabilities q and $1 - q$, respectively. We observe a random vector $X \in \mathbb{R}^L$ with the following distribution: $X | (\eta = i) \sim N(\theta_i, \sigma^2)$; in other words, if $\eta = 0$, then $X \sim N(\theta_0, \sigma^2)$, and if $\varepsilon = 1$, then $X \sim N(\theta_1, \sigma^2)$. If $\theta_1 = 0$, then the latter corresponds to pure noise interval.

We observe X , and our task is to predict η . How well can we do it? First, let us assume without loss of generality that $q \geq 1/2$. Then, if we make the constant prediction $\hat{\eta} \equiv 0$, we will be correct with probability q . So the question is, can we do better than this? We will prove that as $\sigma \rightarrow \infty$, the answer is no. More precisely:

Proposition 3.1. *Let $\hat{\eta}$ be any predictor of η .*

$$\lim_{\sigma \rightarrow \infty} \mathbb{P}[\hat{\eta} = \eta] \leq q.$$

The result is proved in Appendix C.

Proposition 3.1 implies that in order to estimate the signal in low SNR we must consider methods that aim to estimate the signal directly, without estimating the nuisance variables as an intermediate step. In what follows, we present several results on properties of autocorrelations. For simplicity, we consider one-dimensional signals, but the results carry through for higher dimensions.

A one-dimensional signal is determined uniquely by its second- and third-order autocorrelations. Indeed, since $z[0]$ and $z[L - 1]$ are nonzero by definition, we have the formula:

$$z[k] = \frac{z[0]z[k]z[L - 1]}{z[0]z[L - 1]} = \frac{a_z^3[k, L - 1]}{a_z^2[L - 1]}. \quad [8]$$

In particular, we have proven the following proposition:

Proposition 3.2. *A signal $z \in \mathbb{R}^L$ is determined uniquely from a_z^2 and a_z^3 .*

Some remarks are in order. First, Eq. (8) is not numerically stable if $z[0]$ or $z[L - 1]$ are close to 0. In practice, we recover z by fitting it to its autocorrelations using a nonconvex least-squares (LS) procedure, which is empirically more robust to additive noise; we have observed similar phenomena for related problems (34–36). Second, if the separation condition holds, then the length of the signal can be determined from the autocorrelations. In particular, if the separation condition holds for some spacing $W \geq L$, then $a_z^2[i] = 0$ for all $i > L - 1$. Third, note that the second-order autocorrelation is not by itself sufficient to determine the signal uniquely.

However, for dimensions greater than one, almost all signals are determined uniquely up to sign (phase for the complex signals) and reflection through the origin (with conjugation in the complex case). The sign ambiguity can be resolved by the mean of the signal if it is not zero. However, determining the reflection symmetry still requires additional information, beyond the second-order autocorrelation.

The observed moments a_y^1, a_y^2 and a_y^3 of y do not immediately give the moments of the signal x , as seen by Eq. (5), Eq. (6) and Eq. (7); rather, the two are related by the noise level σ and the ratio $\gamma = \lim_{N \rightarrow \infty} ML/N$, [Will: Earlier, you defined gamma in the finite sample case; now it's the limit. These should be made consistent.] where $M = M_N$ grows with N . We will show, however, that x is still identifiable from the observed moments of y . In general, we say a parameter is “identifiable” if its value is uniquely determined in the limit $N \rightarrow \infty$.

First, we observe that if the noise level σ is known, one can estimate γ from the first two moments of the observed vector.

Proposition 3.3. *Let $\sigma > 0$ be fixed. If the mean of x is nonzero, then*

$$\gamma = \lim_{N \rightarrow \infty} \frac{(a_y^1)^2}{\sum_{j=0}^{L-1} a_y^2[j] - \sigma^2} \quad a.s.$$

Proof. The proof follows from plugging the explicit expressions of Eq. (5) and Eq. (6) into the right hand side of the equality. \square

Using third-order autocorrelation information of y , both the ratio γ and the noise σ are identifiable. For the following results, when we say that a result holds for a “generic” signal x , we mean that the set of signals which cannot be determined by these measurements lies in a set with Lebesgue measure zero. In particular, this means that we can recover almost all signals with the given measurements.

Proposition 3.4. *The observed autocorrelations a_y^1, a_y^2 and a_y^3 determine the ratio γ and noise level σ uniquely for a generic signal x . If $\gamma \geq \frac{L}{4(L-1)} \approx \frac{1}{4}$, then this holds for any signal x with nonzero mean.*

Proof. See Appendix D. \square

From Propositions 3.2 and 3.4 we can directly deduce the following:

Corollary 3.5. *The signal x , the ratio γ , and the noise level σ are identifiable from the first three autocorrelation functions of y if:*

- Either the signal x is generic; or
- x has nonzero mean and $\gamma \geq \frac{L}{4(L-1)}$.

4. Numerical experiments

The technique we advocate allows recovery of a signal hidden in noisy micrographs without (even implicitly) [Will: What does this mean?] detecting the location of the signals embedded in these micrographs. To illustrate the underlying principles of the method, we present several numerical examples for the toy model Eq. (1) and a simple proof of concept for simulated

cryo-EM data. Appendix A provides additional details on the experiments.

In the first experiment, we estimated an 50-by-50 pixel image of Einstein with mean zero from a growing number of micrographs, each of size 4096×4096 pixels. Each micrograph contains, on average, 700 occurrences of the target image at random locations. Thus, about 10% of each micrograph contains signal. The micrographs are contaminated with additive white Gaussian noise with standard deviation $\sigma = 3$, corresponding to $\text{SNR} = \frac{M\|x\|_F^2}{\sigma^2 N} \approx 1/370$. This high noise level is illustrated in Figure 1. To simplify the experiment, we assume the number of signal occurrences and the noise standard deviation are known. Micrographs are generated such that any two occurrences are always separated by at least 49 pixels in each direction in accordance with the separation condition.

We compute the average second-order autocorrelation of the micrographs. This is a particularly simple computation which can be efficiently executed with a fast Fourier transform (FFT) on GPUs. Given the noise level and number of image repetitions, the second-order autocorrelation of the image can be easily deduced from Eq. (6). Then, to estimate the target image, we resort to a standard phase retrieval algorithm called relaxed-reflect-reflect (RRR) (37), initialized randomly. Relative error is measured as the ratio of the root mean square error to the norm of the ground truth (square root of the sum of squared pixel intensities).

Figure 2 shows several estimated images for a growing number of micrographs, and a movie is available in [supplementary material]. Figure 3 presents the normalized recovery error as a function of the amount of data available. This is computed after fixing the reflection symmetries (see Section 2). As evidenced by these figures, the ground truth image can be estimated increasingly well from increasingly many micrographs, without particle picking. [Tamir: the experiment is currently running; should be ready tomorrow (Aug 28).]

In practice, we do not expect to know γ and maybe not even σ . Figure 4 shows recovery of a 1-D signal from the first three autocorrelations of the data. The autocorrelations are computed from noisy micrographs with $\sigma = 3$ that obey the separation condition. Both the signal and γ are estimated simultaneously from the observed autocorrelations by LS fitting; more details are given in Appendix A. Crucially, the LS does not require the knowledge of σ .

The application of autocorrelation analysis to cryo-EM follows the same mathematical principles. The derivation of the first three autocorrelations of the micrographs and their relations to the volume itself are provided in Appendix E. In particular, numerical evidence suggests that the third-order autocorrelation uniquely determines the 3-D volume. Figure TKTK shows recovery of the 3-D volume from the clean autocorrelations. The details of the reconstruction algorithm are given in Appendix A. Unfortunately, the mapping between the autocorrelations and volume seems to be ill-conditioned, preventing recovery from noisy data. In the next section, we outline how we suggest to overcome the ill-conditioning in future work.

While we cannot provide a 3-D reconstruction from noisy data with the current algorithm, our method can be easily applied to the problem of deciding whether a micrograph contains projections or merely pure noise—a problem considered in classical works in statistics (e.g., (38)) and debates in the

cryo-EM community (13). This task can be performed by considering solely the recovered γ (the fraction of pixels occupied by projections in the micrograph), estimated as part of the recovery algorithm. Figure 5 presents excerpts [sections?] of two noisy micrographs, only one of which contains projections. In the presence of projections, the estimated γ was 0.12, corresponding to approximately 6784 projections. On the hand, the estimated γ drops to 10^{-5} for the pure noise micrograph, corresponding to less than one projection.

5. Discussion

In the simplified mathematical model we examined, we showed it is possible to estimate a signal without detecting its appearances. Our strategy is to compute autocorrelation functions of the micrographs and to relate these statistics to the unknown signal's parameters. Recovering the parameters from the statistics reduces to solving a set of polynomial equations.

We also showed how this technique can, in principle, be applied to cryo-EM. Crucially, the outlined approach involves no particle picking, hence a fortiori no viewing direction estimation. Concerns for model bias are also greatly reduced since no template matching is involved. Additionally, our technique also allows the use of much lower defocus values. Lower defocus means lower contrast, but will maintain higher frequency information. Consequently, we may be able to get high resolution reconstructions from fewer micrographs.

Looking towards applying the framework to encompass all important features of real cryo-EM experiments, our work implies that it might be possible to reconstruct small molecules, particularly, molecules that are too small to be detected in micrographs. In pursuing this research direction, our goal is to significantly increase the range of molecules to which cryo-EM can be successfully applied. We recognize that significant challenges lay ahead for the implementation of the proposed approach to 3-D reconstruction directly from the micrographs. We discuss a few now.

[First and foremost, we need to mention the sensitivity of the third moment and whether the fourth moment is enough]

One possible concern is that the numerical experiments conducted here suggest a large amount of data may be necessary.* Recent trends in high-throughput cryo-EM technology [?] give hope that this may be a lesser concern in the long term. Still, large amounts of data also require large amounts of computation. On this front, we note that computing autocorrelations can be executed efficiently on CPUs and GPUs, and in parallel across micrographs. It can even be done in streaming mode, as only one pass through each micrograph is necessary. The output of this data processing stage is a succinct summary in the form of autocorrelation estimates: its size is a function of the resolution, not a function of the number of observed micrographs. Subsequent steps, which involve solving the system of polynomial equations, scale only in the size of that summary. Of course, an important question then is whether the equations can be solved meaningfully in practice. The proof-of-concept experiments above suggest they might. [Is it?]

Beyond data acquisition and computational challenges, there are modeling issues to consider. As stated, our approach relies on two core assumptions that are not necessarily

*Whether or not this large amount of data would be necessary for any method to succeed given the unfavorable SNR remains an open question.

Fig. 2. Recovery of Einstein from micrographs at noise level $\sigma = 3$ (see Figure 1(c)). Averaged autocorrelations of the micrographs allow to estimate the power spectrum of the target image. This does not require particle picking. A phase retrieval algorithm (RRR) produces the estimates here shown, initialized randomly. Estimates are obtained from 5×10^2 , 5×10^3 , 5×10^4 micrographs (growing across panels), each containing 700 image occurrences on average. **[XP is still running]**

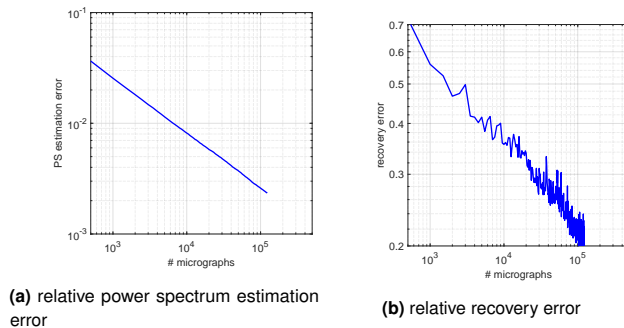

Fig. 3. Error curves for the experiment of Figure 2 **[XP is still running]**

verified in SPR experiments. First, we assume an additive white noise model, while in practice the noise may be correlated or signal dependent. To address this point, it may be necessary to investigate better noise models and to incorporate power spectrum estimation methods. Second, we assume that any two particles are sufficiently separated, and we use this assumption to derive algebraic relations between autocorrelations of the micrographs and autocorrelations of the 3-D volume. We believe that this constraint could be replaced by a probabilistic condition on the average number of projections per micrograph. **[Will: Is this really enough? I think the main issue is what happens when particles can collide (or maybe even overlap), since this introduces additional cross-terms for the moment-fitting problem.]** Such a condition can be met in practice by careful experimental design.

We also note several aspects of SPR experiments that were neglected in this paper, including contrast transfer function (CTF), non-uniformity of the viewing directions **[We never talk about viewing directions at all, so it's strange to mention that non-uniformity is an issue. I think this is confusing. I'd say something like: "relating the observed autocorrelations to the autocorrelations of the 3-D volume" or something like that.]** and other contaminants in the micrographs, such as ice crystals. All these aspects must be taken into account so the method could be applied on real data. We hope to take care of these issues in future research, as well to extend the proposed method to conformational heterogeneity.

Fig. 4. Recovery of a 1-D signal of length $L = 21$ at noise level $\sigma = 3$ from M repetitions. The length of the micrograph was set to be $N = 410 * M$. The first three panels (left to right) show reconstruction with different M values compared to the ground truth signal (in blue). The true value of γ is 0.0512. The relative errors of γ for the three panels are: 27.1%, 4%, 1.2%. The right panel shows the relative error as a function of M .

Fig. 5. All micrographs are of size 7420^2 pixels and the projections are taken from a volume of size 31^3 . The added noise was drawn from i.i.d. Gaussian distribution with zero mean and standard deviation 25, corresponding to an SNR below $1/1024$. The noise realization is identical in both micrographs.

A. Numerical experiments details

2-D experiment. For the 2-D experiment shown in Figures 2 and 3, we generate P micrographs of size 4096×4096 pixels. In each micrograph, we place Einstein’s image (of zero mean) of size 50×50 in random locations, while preserving the separation condition. This is done by randomly selecting 4000 placements in the micrograph, one at a time with an accept/reject rule based on the separation condition and locations picked so far. On average, 700 images are placed in each micrograph. Then, i.i.d. Gaussian noise with standard deviation $\sigma = 3$ is added, inducing an SNR of approximately $1/375$. An example of a micrograph’s excerpt is presented in the right panel of Figure 1.

In this experiment, we assume we know the noise level σ and the total number of occurrences of the target image across all micrographs. In stark contrast with the 1-D setup, the second-order autocorrelation determines almost any target image uniquely, up to reflection through the origin. This is because the second-order autocorrelations correspond to the Fourier magnitudes of the signal through the 2-D Fourier transform. Therefore, we estimate the signal’s Fourier magnitudes (or power spectrum) from the Fourier magnitudes of the micrographs, at the cost of one 2-D fast Fourier transform (FFT) per micrograph. These can be computed highly efficiently and in parallel.

To recover the target image from the estimated power

spectrum, we use a standard phase retrieval algorithm called relaxed-reflect-reflect (RRR). This algorithm iterates the map

$$z \leftarrow z + \beta(P_2(2P_1(z) - z) - P_1(z))$$

on an image z of size $2L \times 2L$. We set the parameter β to 1. The map is designed so that, if the estimated power spectrum is exact, then fixed points contain Einstein's image in the upper-left corner of size $L \times L$, possibly reflected through its origin, and zeros elsewhere. The operator $P_2(z)$ combines the Fourier phases of the current estimation z with the estimated Fourier magnitudes. The operator $P_1(z)$ zeros out all entries of z outside the $L \times L$ upper-left corner. In all experiments, the algorithm halted after a fixed number of 2000 iterations.

1-D experiment. For the 1-D experiment depicted in Figure 4, we used a signal of length $L = 21$ and generated an observation y of length $N = 10(2L - 1)M$, where M is the number of repetitions. The observation was generated by randomly selecting placements in y , one at a time with an accept/reject rule based on the separation condition and locations picked so far until reaching the desired number of signal occurrences. Then, i.i.d. Gaussian noise with mean zero and standard deviation $\sigma = 3$ is added, to form the observed y . The resulting SNR of y is about $1/175$.

Given the observation y , we proceed to compute the autocorrelations. We excluded biased elements of the autocorrelations; that is $a_y^2[\ell_1]$ and $a_y^3[\ell_1, \ell_2]$ such that ℓ_1, ℓ_2 or $\ell_1 - \ell_2$ are zero. This has the practical effect that we need not know σ . By also taking symmetries into account, the third-order autocorrelation contains $\frac{(L-1)(L-2)}{2}$ remaining entries. Thus, in total we have

$$1 + (L - 1) + \frac{(L - 1)(L - 2)}{2} = \frac{1}{2}L(L - 1) + 1$$

coefficients. This redundancy suggests that it might be possible to estimate several signals simultaneously (compare with (35, 39)). In practice, the autocorrelations are computed on disjoint segments of y of length $100 \cdot 10^6$ (if the length of the measurement is larger than that) and added up, without correction for the junction points. Segments are handled sequentially on a GPU, as GPUs are particularly well suited to execute simple instructions across large vectors of data. If multiple GPUs are available, segments can of course be handled in parallel.

Having computed the moments of interest, we now estimate the signal x and coefficient γ which agree with the data. We choose to do so by running an optimization algorithm on the following nonlinear LS problem:

$$\min_{\substack{\hat{x} \in \mathbb{R}^W \\ \gamma > 0}} w_1 (a_y^1 - \gamma a_x^1)^2 + w_2 \sum_{\ell=1}^{L-1} (a_y^2[\ell] - \gamma a_x^2[\ell])^2 + w_3 \sum_{\substack{2 \leq \ell_1 \leq L-1 \\ 1 \leq \ell_2 \leq \ell_1 - 1}} (a_y^3[\ell_1, \ell_2] - \gamma a_x^3[\ell_1, \ell_2])^2, \quad [9]$$

where $W \geq L$ is the length of the sought signals and the weights are set to $w_1 = 1/2, w_2 = 1/2n_2, w_3 = 1/2n_3$, where n_2, n_3 are the number of moments used: $n_2 = L - 1, n_3 = \frac{(L-1)(L-2)}{2}$ (weights could also be set in accordance with variance estimates as in (35)).

Setting $W = L$ (as is a priori desired) is problematic because the above optimization problems appears to have numerous poor local optimizers. Similar phenomenon was recently observed in a related problem (16). Thus, we first run the optimization with $W = 2L - 1$. This problem appears to have few poor local optima, perhaps because the additional degrees of freedom allow for more escape directions. Since we hope the signals estimated this way correspond to the true signals zero-padded to length W , we extract from each one a subsignal of length L that has largest ℓ_2 -norm. This estimator is then used as initial iterate for Eq. (9), this time with $W = L$. We find that this procedure is reliable for a wide range of experimental parameters. To solve Eq. (9), we run the trust-region method implemented in Manopt (40), which allows to treat the positivity constraints on coefficients $\hat{\gamma}$. Notice that the cost function is a polynomial in the variables, so that it is straightforward to compute it and its derivatives.

3-D experiments. For the experiment in Figure TKTK, we computed the analytical first three autocorrelations of the volume according to TKTK. To estimate the coefficients of the volume itself, we solve the LS problem

$$\min_{\hat{x}, \gamma} w_1 |a_x^1 - \gamma a_x^1|^2 + w_2 \|a_x^2 - \gamma a_x^2\|_2^2 + w_3 \|a_x^3 - \gamma a_x^3\|_F^2, \quad [10]$$

where the explicit expressions of a_x^1, a_x^2 and a_x^3 are given in Eq. (64), Eq. (63) and Eq. (62), respectively. In the experiments, we set $w_1 = w_2 = w_3 = 1$.

The LS was solved by TKTK. The expected $\hat{\gamma}$ is one.

In the first experiment, we used [Bla bla bla, real valued volume]

The micrographs for the experiment presented in Figure 5 were generated as follows [separation, etc.]. Then, the LS Eq. (10) was solved with $L = 0$ (low-resolution estimate).

B. Derivation of the identities in Section 2

Throughout the proof, we consider the case of one signal $K = 1$. The extension to $K > 1$ is straightforward by averaging the contributions of all signal with appropriate weights; see (35).

We will let the number of instances of the signal M grow with N , and write $M = M_N$ to emphasize this. We assume M_N grows proportionally with N , and define:

$$\gamma = \lim_{N \rightarrow \infty} \frac{M_N L}{N} < 1. \quad [11]$$

We will assume that $M_N = \Omega(N)$, so that $\gamma > 0$. In the sequel, we will suppress the explicit dependence of M on N for notational convenience.

We start by considering the mean of the data:

$$a_y^1 = \frac{1}{N} \sum_{i=0}^{N-1} y[i] = \frac{1}{N/L} \sum_{j=0}^{M-1} \frac{1}{L} \sum_{i=0}^{L-1} x[i] + \underbrace{\frac{1}{N} \sum_{i=0}^{N-1} \varepsilon[i]}_{\text{noise term}} \xrightarrow{a.s.} \gamma a_x^1, \quad [12]$$

where the noise term converges to zero almost surely (a.s.) by the strong law of large numbers.

We proceed with the (second-order) autocorrelation for fixed $\ell \in [0, \dots, L - 1]$. We can compute:

$$a_y^2[\ell] = \frac{1}{N} \sum_{i=0}^{N-1-\ell} y[i]y[i + \ell]$$

$$\begin{aligned}
&= \underbrace{\frac{1}{N} \sum_{j=1}^M \sum_{i=0}^{L-\ell-1} x[i]x[i+\ell]}_{\text{signal term}} + \underbrace{\frac{1}{N} \sum_{i=0}^{N-1-\ell} \varepsilon[i]\varepsilon[i+\ell]}_{\text{noise term}} \\
&+ \underbrace{\frac{[1, 2?]}{N} \sum_{j=1}^M \sum_{i=0}^{L-1} x[i]\varepsilon[s_j + i + \ell]}_{\text{cross-term}}.
\end{aligned}$$

$$\begin{aligned}
&+ \underbrace{\frac{1}{N} \sum_{j=1}^M \sum_{i=0}^{L-\ell_1+\ell_2-1} \varepsilon[s_j + i]x[i + \ell_1 - \ell_2]x[i]}_{(6)} \\
&+ \underbrace{\frac{1}{N} \sum_{j=1}^M \sum_{i=0}^{L-\ell_2-1} x[i]\varepsilon[s_j + i + \ell_1]x[s_j + i + \ell_2]}_{(7)} \quad [19]
\end{aligned}$$

$$+ \underbrace{\frac{1}{N} \sum_{j=1}^M \sum_{i=0}^{L-\ell_1-1} x[i]x[i + \ell_1]\varepsilon[s_j + i + \ell_2]}_{(8)} \quad [20]$$

The cross-terms are linear in the noise, and are easily shown to vanish almost surely in the limit $N \rightarrow \infty$, by the strong law of large numbers. As for the signal term, we break it into M different sums, each containing one copy of the signal. This gives:

$$\frac{1}{N} \sum_{j=1}^M \sum_{i=0}^{L-\ell-1} x[i]x[i+\ell] = \frac{ML}{N} \frac{1}{L} \sum_{i=0}^{L-\ell-1} x[i]x[i+\ell] \xrightarrow{N \rightarrow \infty} \gamma a_x^2[\ell]. \quad [13]$$

We next analyze the pure noise term. When $\ell \neq 0$, we can break the noise term into a sum of independent terms:

$$\frac{1}{N} \sum_{i=0}^{N-1-\ell} \varepsilon[i]\varepsilon[i+\ell] = \frac{1}{\ell} \sum_{i=0}^{\ell-1} \frac{1}{N/\ell} \sum_{j=0}^{N/\ell-1} \varepsilon[j\ell + i]\varepsilon[(j+1)\ell + i]. \quad [14]$$

Each sum $\frac{1}{N/\ell} \sum_{j=0}^{N/\ell-1} \varepsilon[j\ell + i]\varepsilon[(j+1)\ell + i]$ is an average of N/ℓ independent terms with expectation zero, and thus converges to zero almost surely as $N \rightarrow \infty$. If $\ell = 0$, then we have:

$$\frac{1}{N} \sum_{i=0}^{N-1} \varepsilon^2[i] \xrightarrow{a.s.} \sigma^2. \quad [15]$$

We now analyze the third-order autocorrelation. Let us fix $\ell_1 \geq \ell_2 \geq 0$. We have:

$$\begin{aligned}
a_y^3[\ell_1, \ell_2] &= \frac{1}{N} \sum_{i=0}^{N-1-\ell_1} y[i]y[i+\ell_1]y[i+\ell_2] \\
&= \underbrace{\frac{ML}{N} \frac{1}{M} \sum_{j=1}^M \frac{1}{L} \sum_{i=0}^{L-1-\ell_1} x[i]x[i+\ell_1]x[i+\ell_2]}_{(1)} \quad [16]
\end{aligned}$$

$$\begin{aligned}
&+ \underbrace{\frac{1}{N} \sum_{i=0}^{N-1-\ell_1} \varepsilon[i]\varepsilon[i+\ell_1]\varepsilon[i+\ell_2]}_{(2)} \\
&+ \underbrace{\frac{1}{N} \sum_{j=1}^M \sum_{i=0}^{L-1} x[i]\varepsilon[s_j + i + \ell_1]\varepsilon[s_j + i + \ell_2]}_{(3)} \quad [17]
\end{aligned}$$

$$\begin{aligned}
&+ \underbrace{\frac{1}{N} \sum_{j=1}^M \sum_{i=0}^{L-1} \varepsilon[s_j + i - \ell_1]x[i]\varepsilon[s_j + i + \ell_2 - \ell_1]}_{(4)} \\
&+ \underbrace{\frac{1}{N} \sum_{j=1}^M \sum_{i=0}^{L-1} \varepsilon[s_j + i - \ell_2]\varepsilon[s_j + i + \ell_1 - \ell_2]x[i]}_{(5)} \quad [18]
\end{aligned}$$

Terms (6), (7) and (8) are linear in ε , and can easily be shown to converge to 0 almost surely by the law of large numbers, by similar arguments as used previously. Term (1) converges to $\gamma a_x^3[\ell_1, \ell_2]$ almost surely, for the same reasons as Eq. (13). To deal with terms (2)–(5), we must distinguish between different values of ℓ_1 and ℓ_2 .

Case 1: $0 < \ell_2 < \ell_1$. Here, all summands with elements of ε involve products of distinct entries, which have expected value 0. Consequently, the usual argument shows that terms (2)–(5) all converge to 0 almost surely as $N \rightarrow \infty$.

Case 2: $0 = \ell_2 < \ell_1$. Term (2) is an average of products of the form $\varepsilon[i]^2\varepsilon[i + \ell_1]$, which have mean zero; consequently, term (2) converges to 0 almost surely. The same argument as for Case 1 shows that (3) and (5) also converge to 0. For term (4), we write:

$$\begin{aligned}
&\frac{1}{N} \sum_{j=1}^M \sum_{i=0}^{L-1} \varepsilon[s_j + i - \ell_1]x[i]\varepsilon[s_j + i + \ell_2 - \ell_1] \\
&= \frac{ML}{N} \frac{1}{L} \sum_{i=0}^{L-1} x[i] \frac{1}{M} \sum_{j=1}^M \varepsilon[s_j + i - \ell_1]^2 \\
&\xrightarrow{N \rightarrow \infty} \gamma \frac{1}{L} \sum_{i=0}^{L-1} x[i]\sigma^2 = \gamma a_x^1\sigma^2. \quad [21]
\end{aligned}$$

Case 3: $0 < \ell_2 = \ell_1$. An argument nearly identical to that for Case 2 shows that terms (2), (4) and (5) converge to 0, while term (3) converges to $\gamma a_x^1\sigma^2$.

Case 4: $0 = \ell_2 = \ell_1$. The same argument as for term (4) in Case 2 shows that terms (3), (4) and (5) all converge to $\gamma a_x^1\sigma^2$. Term (2) is an average of $\varepsilon[i]^3$, which is mean zero; consequently, it converges to 0.

This completes the proof.

C. Proof of Proposition 3.1

The proof is based on a variant of the Neyman-Pearson Lemma to derive the best (deterministic) predictor $\hat{\eta}$. We take any predictor $\hat{\eta}$, and we let S be the set of X 's where $\hat{\eta} = 1$. Then the probability that $\hat{\eta}$ fails is:

$$\begin{aligned}
\mathbb{P}[\hat{\eta} \neq \eta] &= q\mathbb{P}_0[\hat{\eta} = 1] + (1-q)\mathbb{P}_1[\hat{\eta} = 0] \\
&= q\mathbb{P}_0[\hat{\eta} = 1] + (1-q)(1 - \mathbb{P}_1[\hat{\eta} = 1]) \\
&= q\mathbb{P}_0[\hat{\eta} = 1] + (1-q) - (1-q)\mathbb{P}_1[\hat{\eta} = 1] \\
&= (1-q) + \int_S (qf_0(x) - (1-q)f_1(x))dx, \quad [22]
\end{aligned}$$

where $f_i(x)$ is the normal density with mean θ_i and variance σ^2 , and the notation \P_i means probability conditional on the event $\eta = \theta_i$; that is, $\P_i[A] = \P[A|\eta = i]$. Let $\Lambda(x) = f_0(x)/f_1(x)$ and $b = (1-q)/q$. The best predictor of η based on X will minimize the integral Eq. (22) and thus [Tamir: Are we sure this is the best?]

$$\eta = \begin{cases} 1, & \text{if } \Lambda(x) \leq b \\ 0, & \text{if } \Lambda(x) \geq b \end{cases} \quad [23]$$

Taking logarithms, the set S can be rewritten as the set of x where:

$$-\|x - \theta_0\|^2 \leq -\|x - \theta_1\|^2 + 2\sigma^2 \log(b),$$

or equivalently

$$\langle x, \theta_1 - \theta_0 \rangle \geq \frac{\|\theta_1\|^2 - \|\theta_0\|^2}{2} - \sigma^2 \log(b).$$

Now let us compute the probability of failure conditional on the event $\eta = 0$. In this case, failure occurs when $X \in S$. Since $X|(\eta = 0) \sim N(\theta_0, \sigma^2)$, we can write $X|(\eta = 0) = \sigma Z + \theta_0$, where $Z \sim N(0, 1)$. Consequently,

$$\begin{aligned} \langle X, \theta_1 - \theta_0 \rangle &= \sigma \langle Z, \theta_1 - \theta_0 \rangle + \langle \theta_0, \theta_1 - \theta_0 \rangle \\ &= \sigma \langle Z, \theta_1 - \theta_0 \rangle + \langle \theta_0, \theta_1 \rangle - \|\theta_0\|^2, \end{aligned}$$

and failure occurs when

$$\begin{aligned} \sigma \langle Z, \theta_1 - \theta_0 \rangle &\geq \frac{\|\theta_1\|^2 - \|\theta_0\|^2}{2} - \langle \theta_0, \theta_1 \rangle - \sigma^2 \log(b) \\ &= \frac{1}{2} \|\theta_1 - \theta_0\|^2 - \sigma^2 \log(b) \end{aligned} \quad [24]$$

or equivalently

$$Y \geq \frac{c}{\sigma} - \sigma^2 \log(b)$$

where $c = \|\theta_1 - \theta_0\|^2/2$ and $Y = \langle Z, \theta_1 - \theta_0 \rangle \sim N(0, \|\theta_1 - \theta_0\|^2)$. Just for simplicity let us assume $\|\theta_1 - \theta_0\| = 1$, so that $Y \sim N(0, 1)$. So:

$$\P_0[\hat{\eta} = 1] = \P\left[Y \geq \frac{c}{\sigma} - \sigma^2 \log(b)\right], \quad Y \sim N(0, 1).$$

Similarly,

$$\P_1[\hat{\eta} = 0] = \P\left[Y \geq \frac{c}{\sigma} + \sigma^2 \log(b)\right], \quad Y \sim N(0, 1).$$

So the overall probability of failure is:

$$\begin{aligned} \P[\hat{\eta} \neq \eta] &= q \P\left[Y \geq \frac{c}{\sigma} - \sigma^2 \log(b)\right] \\ &\quad + (1-q) \P\left[Y \geq \frac{c}{\sigma} + \sigma^2 \log(b)\right]. \end{aligned}$$

Now, if $q = 1/2$, then $\log(b) = 0$. Hence the probability of failure is simply:

$$\P\left[Y \geq \frac{c}{\sigma}\right] \longrightarrow \frac{1}{2} = q \quad \text{as } \sigma \rightarrow \infty. \quad [25]$$

On the other hand, if $q > 1-q$, then $\log(b) < 0$. Then

$$\P\left[Y \geq \frac{c}{\sigma} - \sigma^2 \log(b)\right] \longrightarrow 0 \quad [26]$$

while

$$\P\left[Y \geq \frac{c}{\sigma} + \sigma^2 \log(b)\right] \longrightarrow 1 \quad [27]$$

as $\sigma \rightarrow \infty$. Consequently,

$$\begin{aligned} \P[\hat{\eta} \neq \eta] &= q \P\left[Y \geq \frac{c}{\sigma} - \sigma^2 \log(b)\right] + (1-q) \P\left[Y \geq \frac{c}{\sigma} + \sigma^2 \log(b)\right] \\ &\longrightarrow 1-q \quad \text{as } \sigma \rightarrow \infty. \end{aligned} \quad [28]$$

That is, the probability of success converges to q , which completes the proof. 687
688

D. Proof of Proposition 3.4 689

We will prove that both σ and γ are identifiable from the observed first three moments of y . For convenience, we will work with $\beta = \gamma/L$ rather than γ itself. We will construct two quadratic equations satisfied by β from observed quantities, independent of σ . Then, we will show that these equations are independent, and hence that β is uniquely defined. Given β , we can estimate σ using Proposition 3.3. 690
691
692
693
694
695
696

Throughout the proof, it is important to distinguish between observed and unobserved values. We denote the observed values by E_i or a_y^1, a_y^2, a_y^3 , while using F_i for functions of the signal's autocorrelations. 697
698
699
700

Recall that $a_y^1 = \beta(\mathbf{1}^T x)$ and $a_y^2[0] = \beta\|x\|^2 + \sigma^2$, where $\mathbf{1} \in \mathbb{R}^L$ stands for vector of ones. Taking the product: 701
702

$$\begin{aligned} E_1 &:= a_y^1 a_y^2[0] = (\beta(\mathbf{1}^T x))(\beta\|x\|^2 + \sigma^2) \\ &= \sigma^2 a_y^1 + \beta^2 F_1, \end{aligned} \quad [29] \quad 703$$

where $F_1 := a_x^3[0, 0] + \sum_{j=1}^{L-1} (a_x^3[j, j] + a_x^3[0, j])$. The terms of F_1 can be also estimated from a_y^3 , while taking the scaling and bias terms into account: 704
705
706

$$E_2 := \beta F_1 + (2L+1)\sigma^2 a_y^1. \quad [30] \quad 707$$

Therefore, from Eq. (29) and Eq. (30) we get 708

$$E_2 \beta - (2L+1)\sigma^2 \beta a_y^1 = E_1 - \sigma^2 a_y^1. \quad [31] \quad 709$$

Let $a_y^2 := \sum_{j=0}^{L-1} a_y^2[j]$ and recall from Proposition 3.3: 710

$$\sigma^2 = a_y^2 - (a_y^1)^2/(\beta L). \quad [32] \quad 711$$

Plugging into Eq. (31) and rearranging we get 712

$$\mathcal{A}\beta^2 + \mathcal{B}\beta + \mathcal{C} = 0, \quad [33] \quad 713$$

where

$$\begin{aligned} \mathcal{A} &= E_2 - (2L+1)a_y^1 a_y^2, \\ \mathcal{B} &= -E_1 + \frac{2L+1}{L}(a_y^1)^3 + a_y^1 a_y^2, \\ \mathcal{C} &= -(a_y^1)^3/L. \end{aligned}$$

Importantly, these coefficients are observable quantities. 714

We are now proceeding to derive the second quadratic equation. We notice that 715
716

$$E_3 = \frac{1}{L}(a_y^1)^3 = \frac{1}{L}\beta^3(\mathbf{1}^T x)^3 = \frac{1}{L}\beta^3 F_2, \quad [34] \quad 717$$

where

$$F_2 = a_x^3[0, 0] + 3 \sum_{j=1}^{L-1} a_x^3[j, j] + 3 \sum_{j=1}^{L-1} a_x^3[0, j] + 6 \sum_{1 \leq i < j \leq L-1} a_x^3[i, j].$$

On the other hand, from a_y^3 we can directly estimate F_2 up to scale and bias

$$E_4 = \beta F_2 + (6L - 3)\sigma^2 a_y^1. \quad [35]$$

Taking the ratio:

$$\frac{E_4}{E_3} = \frac{L}{\beta^2} + \frac{(6L - 3)L\sigma^2 a_y^1}{E_3},$$

we conclude:

$$\sigma^2 = \frac{E_4}{a_y^1 L(6L - 3)} - \frac{E_3}{\beta^2 a_y^1 (6L - 3)}.$$

Using Eq. (32) and rearranging we get the second quadratic:

$$\mathcal{D}\beta^2 + \mathcal{E}\beta + \mathcal{F} = 0, \quad [36]$$

where

$$\begin{aligned} \mathcal{D} &= a_y^2 - \frac{E_4}{a_y^1 L(6L - 3)}, \\ \mathcal{E} &= -(a_y^1)^2 / L, \\ \mathcal{F} &= \frac{E_3}{a_y^1 (6L - 3)}. \end{aligned}$$

To complete the proof, we need to show that the two quadratic equations Eq. (33) and Eq. (36) are independent. To this end, it is enough to show that the ratio between the coefficients is not the same. From Eq. (33) and Eq. (29), we have

$$\begin{aligned} \frac{\mathcal{B}}{\mathcal{C}} &= \frac{LE_1 - (2L + 1)(a_y^1)^3 - La_y^1 a_y^2}{(a_y^1)^3} \\ &= \frac{La_y^2[0] - (2L + 1)(a_y^1)^2 - La_y^2}{(a_y^1)^2}. \end{aligned}$$

In addition, using Eq. (34)

$$\frac{\mathcal{E}}{\mathcal{F}} = \frac{(3 - 6L)(a_y^1)^3}{LE_3} = 3 - 6L.$$

Now, suppose that the quadratics are dependent. Then, $\frac{\mathcal{B}}{\mathcal{C}} = \frac{\mathcal{E}}{\mathcal{F}}$, or,

$$La_y^2[0] - (2L + 1)(a_y^1)^2 - La_y^2 = (a_y^1)^2(3 - 6L).$$

Rearranging the equation and writing in terms of x we get

$$4(L - 1)\beta(a_x^1)^2 - \sum_{i=1}^{L-1} a_x^2[i] = 0. \quad [37]$$

For generic x , this polynomial equation is not satisfied. Therefore, the equations are independent. More than that, for any nonzero x , $(a_x^1)^2 > \sum_{i=1}^{L-1} a_x^2[i]$. Therefore, if $4(L - 1)\beta \geq 1$, or,

$$\beta \geq \frac{1}{4(L - 1)},$$

the condition Eq. (37) cannot be satisfied for any signal.

E. Autocorrelations of the cryo-EM problem

A. Model and autocorrelation functions. Let ϕ be the Coulomb potential representing the molecule we aim to recover. We assume that molecule is real-valued and smooth. In spherical coordinates, its 3-D Fourier transform $\hat{\phi}$ admits a finite expansion of the form

$$\hat{\phi}(k, \theta, \varphi) = \sum_{\ell=0}^L \sum_{m=-\ell}^{\ell} \sum_{s=1}^{S(\ell)} x_{\ell, m, s} Y_{\ell}^m(\theta, \varphi) j_{\ell, s}(k), \quad [38]$$

where Y_{ℓ}^m are complex spherical harmonics and $j_{\ell, s}$ are normalized spherical Bessel functions; see Appendix TKTK for further definitions. Let I_{ω} denote the tomographic projection obtained from viewing direction $\omega \in SO(3)$. By the Fourier projection-slice theorem, its 2-D Fourier transform is given by (41):

$$\hat{I}_{\omega}(k, \varphi) = \sum_{\ell, m, m', s} x_{\ell, m, s} D_{m', m}^{\ell}(\omega) Y_{\ell}^{m'}\left(\frac{\pi}{2}, \varphi\right) j_{\ell, s}(k), \quad [39]$$

where $D_{m', m}^{\ell}(\omega)$ is a Wigner-D matrix.

Let $\mathcal{I} \in \mathbb{R}^{N \times N}$ denote a micrograph. We assume it consists of shifted copies of projections contaminated by additive white Gaussian noise:

$$\mathcal{I} = \sum_{t=1}^M I_{\omega_t} * \delta_{\mathbf{s}_t} + \varepsilon, \quad \varepsilon \sim \mathcal{N}(0, \sigma^2 I), \quad [40]$$

where the viewing directions ω_t are assumed to be drawn from the uniform distribution over $SO(3)$ and \mathbf{s}_t denotes the location of the center of the t th projection in the micrograph. Again, we impose a separation condition so that any two projections are separated by at least $2P - 1$ pixels between their upper left corners in each direction. Note that Eq. (1) can be also written as a sum of δ functions as in Eq. (40).

Define the p th autocorrelation of \mathcal{I} as

$$a_{\mathcal{I}}^p(\ell_1, \dots, \ell_{p-1}) = \frac{1}{N^2} \sum_{\mathbf{i}} \mathcal{I}[\ell] \mathcal{I}[\mathbf{i} + \ell_1] \cdots \mathcal{I}[\mathbf{i} + \ell_{p-1}],$$

where the summation is for \mathbf{i} ranging over the N^2 pixels of the micrograph. Let $\mathcal{I}_1, \dots, \mathcal{I}_K$ denote a set of K micrographs. Under the specified conditions, we show in Appendix B that the first three autocorrelations of the micrographs are related to those of the projections by

$$\lim_{K \rightarrow \infty} \frac{1}{K} \sum_{i=1}^K a_{\mathcal{I}_i}^p[\ell_1, \dots, \ell_{p-1}] = \gamma \langle a_{I_{\omega}}^p[\ell_1, \dots, \ell_{p-1}] \rangle_{\omega} \quad [41]$$

$$+ b_p[\ell_1, \dots, \ell_{p-1}], \quad [42]$$

$$p = 1, 2, 3, \quad \ell_1, \dots, \ell_{p-1} \in [-(P - 1), P - 1]^2,$$

where $\langle \cdot \rangle_{\omega}$ denotes averaging over all possible viewing directions ω and b_p is a bias term. Specifically, $b_1 = 0$ and therefore the mean is unbiased. The bias term of the second-order autocorrelation b_2 depends only on σ^2 , the variance of the noise. Hence, if the noise level can be accurately estimated from the micrographs, this bias can be removed. Finally, the bias term of the third-order autocorrelation b_3 depends on the mean of the micrograph and σ^2 . Therefore, given sufficiently many projections, we can accurately estimate the quantities $\gamma \langle a_{I_{\omega}}^p \rangle_{\omega}$ directly from the micrographs. These quantities are functions

of the unknown coefficients $x_{l,m,s}$ and we could proceed to invert their relation, as we did in the 2-D toy example.

In practice, we want to leverage one more feature of the 3-D reconstruction problem. Since all in-plane rotations of the micrographs are equally likely observations, it is desirable in Eq. (41) to average over all in-plane rotations as well. This can be done efficiently using Prolate Spheroidal Wave Functions (PSWFs). We use autocorrelations up to and including the third order since this is necessary to determine the volume. The details are in the appendix.

B. Moments derivation. In this section we prove relation Eq. (41). We note that mathematically taking infinitely many micrographs is equivalent to take one infinitely large micrograph with fixed density γ Eq. (??). Hence, we consider the moments of one micrograph \mathcal{I} in the limit $N \rightarrow \infty$ and $\gamma = \lim_{N \rightarrow \infty} \frac{MP^2}{N^2} \in (0, 1)$. The separation condition guarantees that if $\mathbf{i} = (i, j)$ is in the support of some projection, then $\mathbf{i} + \boldsymbol{\ell}$ for $\boldsymbol{\ell} \in [-(P-1), P-1]^2$ is either in the support of the same projection or outside the support of any projection.

We begin by calculating the relation between the p th autocorrelation of the clean micrograph and the averaged autocorrelation of the projections. Let us denote the clean micrograph by $\tilde{\mathcal{I}} = \mathcal{I} - \varepsilon$, where \mathcal{I} and ε are given in Eq. (40). Denote by \mathcal{S}_t the support of the t th particle. Then, we have

$$\begin{aligned} a_{\mathcal{I}}^p[\ell_1, \dots, \ell_{p-1}] &= \frac{1}{N^2} \sum_{\mathbf{i}} \tilde{\mathcal{I}}[\mathbf{i}] \tilde{\mathcal{I}}[\mathbf{i} + \boldsymbol{\ell}_1] \cdots \tilde{\mathcal{I}}[\mathbf{i} + \boldsymbol{\ell}_{p-1}] \\ &= \frac{1}{N^2} \sum_{t=1}^M \sum_{\mathbf{i} \in \mathcal{S}_t} \tilde{\mathcal{I}}[\mathbf{i}] \tilde{\mathcal{I}}[\mathbf{i} + \boldsymbol{\ell}_1] \cdots \tilde{\mathcal{I}}[\mathbf{i} + \boldsymbol{\ell}_{p-1}] \\ &= \frac{MP^2}{N^2} \cdot \frac{1}{M} \sum_{t=1}^M \frac{1}{P^2} \sum_{\mathbf{i}, j=0}^{P-1} I_{\omega_t}[\mathbf{i}] I_{\omega_t}[\mathbf{i} + \boldsymbol{\ell}_1] \cdots I_{\omega_t}[\mathbf{i} + \boldsymbol{\ell}_{p-1}] \\ &= \frac{MP^2}{N^2} \frac{1}{M} \sum_{t=1}^M a_{I_{\omega_t}}^p[\ell_1, \dots, \ell_{p-1}] \\ &\rightarrow \gamma \langle a_{I_{\omega}}^p[\ell_1, \dots, \ell_{p-1}] \rangle_{\omega}, \end{aligned} \quad [43]$$

where the average is taken over ω with respect to the distribution of viewing directions. Here, we assume it to be uniform.

In the presence of noise, we get additional bias terms denoted by b_p in Eq. (41). The mean ($p = 1$) is unbiased since the noise is assumed to have zero mean. For the second-order autocorrelation ($p = 2$), we have

$$\begin{aligned} a_{\mathcal{I}}^2[\boldsymbol{\ell}] &= \frac{1}{N^2} \sum_{\mathbf{i}} \mathcal{I}[\mathbf{i}] \mathcal{I}[\mathbf{i} + \boldsymbol{\ell}] \\ &= \frac{1}{N^2} \sum_{\mathbf{i}} \tilde{\mathcal{I}}[\mathbf{i}] \tilde{\mathcal{I}}[\mathbf{i} + \boldsymbol{\ell}] + \frac{1}{N^2} \sum_{\mathbf{i}} \tilde{\mathcal{I}}[\mathbf{i}] \varepsilon[\mathbf{i} + \boldsymbol{\ell}] \\ &\quad + \frac{1}{N^2} \sum_{\mathbf{i}} \varepsilon[\mathbf{i}] \tilde{\mathcal{I}}[\mathbf{i} + \boldsymbol{\ell}] + \frac{1}{N^2} \sum_{\mathbf{i}} \varepsilon[\mathbf{i}] \varepsilon[\mathbf{i} + \boldsymbol{\ell}]. \end{aligned}$$

The first term is given by Eq. (43) for $p = 2$. The cross terms vanish in the limit. The fourth term is zero unless $\boldsymbol{\ell} = 0$, in which case it converges to σ^2 . Thus, we conclude

$$a_{\mathcal{I}}^2[\boldsymbol{\ell}] \rightarrow \gamma \langle a_{I_{\omega}}^2[\boldsymbol{\ell}] \rangle_{\omega} + \sigma^2 \delta[\boldsymbol{\ell}], \quad [44]$$

where the bias term $b_2[\boldsymbol{\ell}] = \sigma^2 \delta[\boldsymbol{\ell}]$ depends only on the variance of the noise σ^2 .

For the third moments, we get 8 terms:

$$\begin{aligned} a_{\mathcal{I}}^3[\ell_1, \ell_2] &= \underbrace{\frac{1}{N^2} \sum_{\mathbf{i}} \tilde{\mathcal{I}}[\mathbf{i}] \tilde{\mathcal{I}}[\mathbf{i} + \boldsymbol{\ell}_1] \tilde{\mathcal{I}}[\mathbf{i} + \boldsymbol{\ell}_2]}_{(1)} + \underbrace{\frac{1}{N^2} \sum_{\mathbf{i}} \varepsilon[\mathbf{i}] \varepsilon[\mathbf{i} + \boldsymbol{\ell}_1] \varepsilon[\mathbf{i} + \boldsymbol{\ell}_2]}_{(2)} \\ &\quad + \underbrace{\frac{1}{N^2} \sum_{\mathbf{i}} \tilde{\mathcal{I}}[\mathbf{i}] \varepsilon[\mathbf{i} + \boldsymbol{\ell}_1] \tilde{\mathcal{I}}[\mathbf{i} + \boldsymbol{\ell}_2]}_{(3)} + \underbrace{\frac{1}{N^2} \sum_{\mathbf{i}} \tilde{\mathcal{I}}[\mathbf{i}] \tilde{\mathcal{I}}[\mathbf{i} + \boldsymbol{\ell}_1] \varepsilon[\mathbf{i} + \boldsymbol{\ell}_2]}_{(4)} \\ &\quad + \underbrace{\frac{1}{N^2} \sum_{\mathbf{i}} \varepsilon[\mathbf{i}] \tilde{\mathcal{I}}[\mathbf{i} + \boldsymbol{\ell}_1] \tilde{\mathcal{I}}[\mathbf{i} + \boldsymbol{\ell}_2]}_{(5)} + \underbrace{\frac{1}{N^2} \sum_{\mathbf{i}} \tilde{\mathcal{I}}[\mathbf{i}] \varepsilon[\mathbf{i} + \boldsymbol{\ell}_1] \varepsilon[\mathbf{i} + \boldsymbol{\ell}_2]}_{(6)} \\ &\quad + \underbrace{\frac{1}{N^2} \sum_{\mathbf{i}} \varepsilon[\mathbf{i}] \varepsilon[\mathbf{i} + \boldsymbol{\ell}_1] \tilde{\mathcal{I}}[\mathbf{i} + \boldsymbol{\ell}_2]}_{(7)} + \underbrace{\frac{1}{N^2} \sum_{\mathbf{i}} \varepsilon[\mathbf{i}] \tilde{\mathcal{I}}[\mathbf{i} + \boldsymbol{\ell}_1] \varepsilon[\mathbf{i} + \boldsymbol{\ell}_2]}_{(8)}. \end{aligned}$$

We address these terms one by one:

- Term (1) is treated by Eq. (43) for $p = 3$;
- Term (2) is the third-order autocorrelation of pure noise which vanishes in the limit;
- Terms (3)-(5) depend linearly on the noise and hence vanish in the limit;
- For term (6), if $\ell_1 \neq \ell_2$ the term vanishes in the limit. If $\ell_1 = \ell_2$ then

$$\begin{aligned} \frac{1}{N^2} \sum_{\mathbf{i}} \tilde{\mathcal{I}}[\mathbf{i}] \varepsilon[\mathbf{i} + \boldsymbol{\ell}]^2 &= \frac{MP^2}{N^2} \cdot \frac{1}{MP^2} \sum_{t=1}^M \sum_{\mathbf{i} \in \mathcal{S}_t} I_{\omega_t}[\mathbf{i}] \varepsilon[\mathbf{i} + \boldsymbol{\ell}]^2 \\ &\rightarrow \gamma \sigma^2 \langle a_{I_{\omega}}^1 \rangle_{\omega}, \end{aligned}$$

where $\langle a_{I_{\omega}}^1 \rangle_{\omega}$ is the mean of the volume.

- Terms (7) and (8) contribute δ functions similar to (6).

Thus, we conclude that

$$a_{\mathcal{I}}^3[\ell_1, \ell_2] \rightarrow \gamma \langle a_{I_{\omega}}^3[\ell_1, \ell_2] \rangle_{\omega} + \gamma \sigma^2 \langle a_{I_{\omega}}^1 \rangle_{\omega} \left(\delta[\ell_1 - \ell_2] + \delta[\ell_1] + \delta[\ell_2] \right), \quad [45]$$

where the second term is the bias $b_3[\ell_1, \ell_2]$. Note that $\gamma \langle a_{I_{\omega}}^1 \rangle_{\omega}$ is approximately the mean of the micrograph since $a_{\mathcal{I}}^1 \approx a_{\mathcal{I}}^1 \approx \gamma \langle a_{I_{\omega}}^1 \rangle_{\omega}$. Therefore, we do not need prior knowledge of γ to effectively debias the third-order autocorrelation.

C. Accounting for all in-plane rotations. We represent our autocorrelations using Prolate Spheroidal Wave Functions (PSWFs) $\{\psi_{k,q}\}$ where $k \geq 0, q \geq 1$ are integers (42). As we demonstrate below, this makes it easier to account for the fact that all in-plane rotations of the micrographs are equally likely observations. This is only a concern for the second and third order autocorrelations. Below, we start with $p = 2$. The PSWFs are eigenfunctions of the truncated Fourier transform and are given in polar coordinates by

$$\psi_{k,q}(r, \varphi) = \begin{cases} \frac{1}{\sqrt{8\pi}} \alpha_{k,q} R_{k,q}(r) e^{i k \varphi}, & r \leq 1, \\ 0, & r > 1, \end{cases} \quad [46]$$

[Ref eq. 8 in Boris' paper] where the $R_{k,q}$ are a family of real, one-dimensional functions and the $\alpha_{k,q}$ are scaling factors

which will be defined in the next section. The PSWFs are orthogonal on the unit disk.

For $\ell \in [-(P-1), P-1]^2$, let us define

$$a^2[k, q] = \sum_{\ell} a_{\mathcal{I}}^2[\ell] \overline{\psi_{k,q}[\ell]}, \quad [47]$$

where $\psi_{k,q}[\ell] := \psi_{k,q}(\ell/(P-1))$ is a discretization of the PSWFs. [Range of k, q ? need approx orthonormality in discrete...] Knowledge of these coefficients is essentially equivalent to knowledge of the second-order correlations owing to the following approximate identity:

$$a_{\mathcal{I}}^2[\ell] \approx \sum_{k,q} a^2[k, q] \psi_{k,q}[\ell]. \quad [48]$$

This holds because the continuous PSWFs form an orthogonal basis, and their discretized counterparts are (empirically) almost orthogonal. As a result, for our purposes, the pair of equations above provides a basis expansion for the autocorrelations.

We now proceed to show that the coefficients $a^2[k, q]$ can be computed from the micrographs directly. By definition,

$$\begin{aligned} a^2[k, q] &= \sum_{\ell} a_{\mathcal{I}}^2[\ell] \overline{\psi_{k,q}[\ell]} \\ &= \frac{1}{N^2} \sum_{\mathbf{i}} \mathcal{I}[\mathbf{i}] \left(\sum_{\ell} \mathcal{I}[\mathbf{i} + \ell] \overline{\psi_{k,q}[\ell]} \right) \\ &= \frac{1}{N^2} \sum_{\mathbf{i}} \mathcal{I}[\mathbf{i}] a_{k,q}[\mathbf{i}], \end{aligned} \quad [49]$$

where we defined

$$a_{k,q}[\mathbf{i}] = \sum_{\ell} \mathcal{I}[\mathbf{i} + \ell] \overline{\psi_{k,q}[\ell]}. \quad [50]$$

These coefficients can be computed efficiently. Indeed, consider a patch of the micrograph \mathcal{I} centered around pixel \mathbf{i} and of size $(2P-1) \times (2P-1)$. This is exactly the patch indexed in the sum above. Hence, using the same approximation as we did in Eq. (48), a direct expansion of that patch in the discretized PSWFs yields the sought coefficients:

$$\mathcal{I}[\mathbf{i} + \ell] \approx \sum_{k,q} a_{k,q}[\mathbf{i}] \psi_{k,q}[\ell]. \quad [51]$$

Thus, we proceed as follows: for each position \mathbf{i} in the micrograph \mathcal{I} , we extract the corresponding patch of size $2P-1$, expand it in the discretized PSWFs as in Eq. (51), and collect the $a_{k,q}$ as per Eq. (49) to constitute the second-order autocorrelation of the micrograph.

Crucially, following this formalism, it is now straightforward to account for all in-plane rotations and reflections of the micrograph. Indeed, as can be seen from the definition of the (continuous) PSWFs Eq. (46), the effects of rotations and reflections on expansion coefficients of real images are, respectively, phase modulation and conjugation: this is why this the PSWF basis is called *steerable* (43, 44). By analogy in the discrete case, we have the following approximate expansions for a patch rotated about its center \mathbf{i} by an angle α :

$$\mathcal{I}^{\alpha,+}[\mathbf{i} + \ell] \approx \sum_{k,q} a_{k,q} e^{-\iota k \alpha} \psi_{k,q}[\ell],$$

and the reflection followed by a rotation by angle α :

$$\mathcal{I}^{\alpha,-}[\mathbf{i} + \ell] \approx \sum_{k,q} \overline{a_{k,q}} e^{-\iota k \alpha} \psi_{k,q}[\ell].$$

Averaging over all rotations of the patch $\mathcal{I}(\mathbf{i} + \Delta \mathbf{i})$ and its reflection we get

$$\begin{aligned} a^2[k, q] &= \frac{1}{N^2} \sum_{\mathbf{i}} \mathcal{I}[\mathbf{i}] \left(\frac{1}{4\pi} \int_0^{2\pi} (a_{k,q}[\mathbf{i}] + \overline{a_{k,q}[\mathbf{i}]}) e^{-\iota k \alpha} d\alpha \right) \\ &= \delta[k] \frac{1}{N^2} \sum_{\mathbf{i}} \mathcal{I}[\mathbf{i}] a_{0,q}[\mathbf{i}], \end{aligned} \quad [52]$$

where in the last equality we used that $a_{0,q}[\mathbf{i}]$ is real since both \mathcal{I} and $\psi_{0,q}$ are real valued (more generally, $a_{-k,q} = \overline{a_{k,q}}$). Thus, the second-order autocorrelation, though two-dimensional, effectively only provides radial information.

We now follow a similar approach to estimate the bias term b_2 . Introduce the coefficients b_2 as:

$$\begin{aligned} b_2[k, q] &= \sigma^2 \sum_{\ell} \delta[\ell] \overline{\psi_{k,q}[\ell]} \\ &= \sigma^2 \overline{\psi_{k,q}[\mathbf{0}]} \\ &= \delta[k] \frac{\sigma^2}{\sqrt{2\pi}} R_{0,q}(0), \end{aligned}$$

where we used the fact that the functions $R_{k,q}$ are zero at the origin for $k \neq 0$. With this definition, we have the usual approximation:

$$b_2[\ell] = \sigma^2 \delta[\ell] \approx \sum_{k,q} b_2[k, q] \psi_{k,q}[\ell].$$

We now turn our attention to the third order autocorrelation. Following the same lines, we define the coefficients:

$$\begin{aligned} a^3[k_1, q_1; k_2, q_2] &= \sum_{\ell_1, \ell_2} a_{\mathcal{I}}^3[\ell_1, \ell_2] \overline{\psi_{k_1, q_1}[\ell_1]} \overline{\psi_{k_2, q_2}[\ell_2]} \\ &= \frac{1}{N^2} \sum_{\mathbf{i}} \mathcal{I}[\mathbf{i}] \left(\sum_{\ell_1} \mathcal{I}[\mathbf{i} + \ell_1] \overline{\psi_{k_1, q_1}[\ell_1]} \right) \\ &\quad \times \left(\sum_{\ell_2} \mathcal{I}[\mathbf{i} + \ell_2] \overline{\psi_{k_2, q_2}[\ell_2]} \right) \\ &= \frac{1}{N^2} \sum_{\mathbf{i}} \mathcal{I}[\mathbf{i}] a_{k_1, q_1}[\mathbf{i}] \overline{a_{k_2, q_2}[\mathbf{i}]}, \end{aligned}$$

where the patch expansion coefficients $a_{k,q}$ are as defined in Eq. (50). The coefficients $a^3[k_1, q_1; k_2, q_2]$ are related to the third-order autocorrelation via the approximate identity:

$$a_{\mathcal{I}}^3[\ell_1, \ell_2] \approx \sum_{\substack{k_1, q_1 \\ k_2, q_2}} a^3[k_1, q_1; k_2, q_2] \psi_{k_1, q_1}[\ell_1] \overline{\psi_{k_2, q_2}[\ell_2]}.$$

Averaging over all rotations of \mathcal{I} and its reflection, we obtain

$$\begin{aligned} a^3[k_1, q_1; k_2, q_2] &= \frac{1}{N^2} \sum_{\mathbf{i}} \mathcal{I}[\mathbf{i}] \left(\frac{1}{4\pi} \int_0^{2\pi} (a_{k_1, q_1}[\mathbf{i}] \overline{a_{k_2, q_2}[\mathbf{i}]} + \overline{a_{k_1, q_1}[\mathbf{i}]} a_{k_2, q_2}[\mathbf{i}]) e^{-\iota(k_1 - k_2)\alpha} d\alpha \right) \\ &= \delta[k_1 - k_2] \frac{1}{N^2} \sum_{\mathbf{i}} \mathcal{I}[\mathbf{i}] \Re\{a_{k_1, q_1}[\mathbf{i}] \overline{a_{k_2, q_2}[\mathbf{i}]} \}. \end{aligned} \quad [54]$$

Thus, similarly to the second-order autocorrelation, averaging over all in-plane rotations reveals that the 4-D third-order autocorrelation truly only carries information along three dimensions.

Finally, we treat the bias terms, using approximate orthonormality [9] of the discretized PSFWs:

$$\begin{aligned} b_3[k_1, q_1; k_2, q_2] &= \gamma \sigma^2 \langle a_{I_\omega}^1 \rangle_\omega \delta[k_1 - k_2] \\ &\times \left[\delta[q_1 - q_2] + \delta[k_1] \frac{1}{2\pi} (\alpha_{0,q_1} + \alpha_{0,q_2}) R_{0,q_1}(0) R_{0,q_2}(0) \right]. \end{aligned}$$

Thus,

$$\begin{aligned} b_3[\ell_1, \ell_2] &= \gamma \sigma^2 \langle a_{I_\omega}^1 \rangle_\omega \left(\delta[\ell_1 - \ell_2] + \delta[\ell_1] + \delta[\ell_2] \right) \\ &\approx \sum_{\substack{k_1, q_1 \\ k_2, q_2}} b_3[k_1, q_1; k_2, q_2] \psi_{k_1, q_1}[\ell_1] \overline{\psi_{k_2, q_2}[\ell_2]}. \end{aligned}$$

D. Connection to volume. Until now, we have established simple relations between the autocorrelations of the micrographs and the autocorrelations of the volume. Now, we complete the picture by deriving the connection with the volume itself.

We start by some preliminary computations. Let us expand the Fourier transform of the volume as

$$\widehat{\phi}(ck, \theta, \varphi) = \sum_{\ell=0}^L \sum_{m=-\ell}^{\ell} \sum_{s=1}^{S(\ell)} x_{\ell, m, s} Y_{\ell, m}^m(\theta, \varphi) j_{\ell, s}(k), \quad k \leq 1, \quad [55]$$

[How do we choose $S(\ell)$?] where c is the bandlimit, $j_{\ell, s}$ is the normalized spherical Bessel functions given by

$$j_{\ell, s}(k) = \frac{4}{[j_{\ell+1}(u_{\ell, s})]} j_{\ell}(2u_{\ell, s}k),$$

j_{ℓ} is the spherical Bessel function of order ℓ and $u_{\ell, s}$ is the s th positive zero of j_{ℓ} . We use the complex spherical harmonics Y_{ℓ}^m defined by

$$Y_{\ell, m}(\theta, \varphi) := \sqrt{\frac{2\ell+1}{4\pi} \cdot \frac{(\ell-m)!}{(\ell+m)!}} P_{\ell}^m(\cos \theta) e^{im\varphi},$$

where P_{ℓ}^m are the associated Legendre polynomials with the Condon-Shortley phase. Sampling at the Nyquist-rate dictates $k \in [0, 1/2]$ (45). [Didn't we say that $k \leq 1$?] With this notation, the Fourier transform of a projection taken from the viewing direction $\omega \in SO(3)$ can be written as

$$\widehat{I}_{\omega}(ck, \theta) = \sum_{\ell, m, m', s} x_{\ell, m, s} Y_{\ell, m'}(\pi/2, 0) D_{m', m}^{\ell}(\omega) j_{\ell, s}(k) e^{im'\theta}.$$

Recall that the PSFWs are the solution of the integral equation [To mention the range of \mathbf{r} ?]

$$\alpha_{N, n} \psi_{N, n}(\mathbf{k}) = \int_{\mathbf{r}} \psi_{N, n}(\mathbf{r}) e^{i\mathbf{c}(\mathbf{r} \cdot \mathbf{k})} d\mathbf{r}, \quad [56]$$

and are given explicitly by [Do we use this normalization?]

$$\psi_{N, n}(k, \theta) = \frac{1}{\sqrt{2\pi}} R_{N, n}(k) e^{iN\theta},$$

where $R_{N, n}(k)$ is a solution to another integral equation (43). Let us assume that I_{ω} has bandlimit c and is concentrated

in the unit ball in real space. Using the 2-D PSFWs, we can express each projection as

$$\widehat{I}_{\omega}(ck, \theta) = \sum_{N, n} b_{N, n}(\omega) \psi_{N, n}(k, \theta),$$

where

$$\begin{aligned} b_{N, n}(\omega) &= \frac{1}{\sqrt{2\pi}} \int_0^{2\pi} \int_0^1 \widehat{I}_{\omega}(ck, \theta) R_{N, n}(k) e^{-iN\theta} k dk d\theta, \\ &= \sum_{\ell, m, m', s} x_{\ell, m, s} \left[\sqrt{2\pi} Y_{\ell, m'}(\pi/2, 0) \right] D_{m', m}^{\ell}(\omega) \\ &\times \left(\int_0^1 j_{\ell, s}(k) R_{N, n}(k) k dk \right) \left(\frac{1}{2\pi} \int_0^{2\pi} e^{i(m'-N)\theta} d\theta \right), \\ &= \sum_{|N| \leq \ell} \sum_{m, s} x_{\ell, m, s} D_{N, m}^{\ell}(\omega) \beta_{\ell, s; N, n}, \end{aligned} \quad [57]$$

where the coefficients

$$\beta_{\ell, s; N, n} := \begin{cases} \sqrt{2\pi} Y_{\ell, N}(\pi/2, 0) \int_0^1 j_{\ell, s}(k) R_{N, n}(k) k dk, & \ell \geq |N| \\ 0, & \ell < |N| \end{cases}, \quad [57]$$

can be precomputed. Since the PSFWs are eigenfunctions of the truncated Fourier operator Eq. (56), we can now express the projection in real space as

$$\begin{aligned} I_{\omega}(r, \varphi) &= \sum_{N, n} \widehat{\alpha}_{N, n} b_{N, n}(\omega) \psi_{N, n}(r, \varphi) \\ &= \sum_{\ell=0}^L \sum_{N, m=-\ell}^{\ell} \sum_{n=0}^{n_{\max}(N)} \sum_{s=1}^{S(\ell)} x_{\ell, m, s} \widehat{\beta}_{\ell, s; N, n} D_{N, m}^{\ell}(\omega) \psi_{N, n}(r, \varphi) \end{aligned} \quad [58]$$

[How do we choose n_{\max} ?] where $\alpha_{N, n}$ is the eigenvalue corresponding to the (N, n) th PSWF, $\widehat{\alpha}_{N, n} = (c/2\pi)^2 \alpha_{N, n}$, and $\widehat{\beta}_{\ell, s; N, n} = \widehat{\alpha}_{N, n} \beta_{\ell, s; N, n}$.

Third-order autocorrelation. In Eq. (45) and Eq. (53) we have shown how the third-order autocorrelations of the micrographs and the volume are related, and how we can present them in PSFWs. Now, we relate these expressions to the expansion coefficients of the volume itself.

The third-order autocorrelation of the volume can be expressed in terms of Eq. (58): [What about the $\widehat{\alpha}$ coefficients?]

$$\begin{aligned} \langle a_{I_{\omega}}^3[\ell_1, \ell_2] \rangle_{\omega} &= \frac{1}{L^2} \sum_{\mathbf{i}} \langle I_{\omega}[\mathbf{i}] I_{\omega}[\mathbf{i} + \ell_1] I_{\omega}[\overline{[\mathbf{i} + \ell_2]}] \rangle_{\omega}, \\ &\approx \sum_{\substack{N_1, n_1 \\ N_2, n_2 \\ N_3, n_3}} \langle b_{N_1, n_1}(\omega) b_{N_2, n_2}(\omega) \overline{b_{N_3, n_3}(\omega)} \rangle_{\omega} \\ &\times \frac{1}{L^2} \sum_{\mathbf{i}} \psi_{N_1, n_1}[\mathbf{i}] \psi_{N_2, n_2}[\mathbf{i} + \ell_1] \overline{\psi_{N_3, n_3}[\overline{[\mathbf{i} + \ell_2]}]}, \end{aligned} \quad [59]$$

where the approximation is due to discretization. Now,

$$\begin{aligned} &\langle b_{N_1, n_1}(\omega) b_{N_2, n_2}(\omega) \overline{b_{N_3, n_3}(\omega)} \rangle_{\omega} \\ &= \sum_{\substack{\ell_1, m_1, s_1 \\ \ell_2, m_2, s_2 \\ \ell_3, m_3, s_3}} x_{\ell_1, m_1, s_1} x_{\ell_2, m_2, s_2} \overline{x_{\ell_3, m_3, s_3}} \\ &\times \langle D_{N_1, m_1}^{\ell_1}(\omega) D_{N_2, m_2}^{\ell_2}(\omega) \overline{D_{N_3, m_3}^{\ell_3}(\omega)} \rangle_{\omega} \\ &\times \beta_{\ell_1, s_1; N_1, n_1} \beta_{\ell_2, s_2; N_2, n_2} \overline{\beta_{\ell_3, s_3; N_3, n_3}}, \end{aligned}$$

where the latter coefficients are given explicitly in Eq. (57). Using standard properties of D-Wigner functions, we obtain

$$\left\langle D_{N_1, m_1}^{\ell_1}(\omega) D_{N_2, m_2}^{\ell_2} \overline{D_{N_3, m_3}^{\ell_3}} \right\rangle_{\omega} = (-1)^{N_3 + m_3} \quad [60]$$

$$\times \begin{pmatrix} \ell_1 & \ell_2 & \ell_3 \\ N_1 & N_2 & -N_3 \end{pmatrix} \begin{pmatrix} \ell_1 & \ell_2 & \ell_3 \\ m_1 & m_2 & -m_3 \end{pmatrix},$$

where $\begin{pmatrix} \ell_1 & \ell_2 & \ell_3 \\ m_1 & m_2 & m_3 \end{pmatrix}$ are called Wigner 3-j symbols. Notably, these terms are zero unless $m_1 + m_2 + m_3 = 0$ and $|\ell_1 - \ell_2| \leq \ell_3 \leq \ell_1 + \ell_2$. Thus, we conclude that

$$\langle b_{N_1, n_1}(\omega) b_{N_2, n_2}(\omega) \overline{b_{N_3, n_3}(\omega)} \rangle_{\omega} = \delta_{N_3, N_1 + N_2} \quad [61]$$

$$\times \sum_{\substack{\ell_1, m_1, s_1 \\ \ell_2, m_2, s_2 \\ s_3}}^{\min(L, \ell_1 + \ell_2)} \sum_{\ell_3 = |\ell_1 - \ell_2|} x_{\ell_1, m_1, s_1} x_{\ell_2, m_2, s_2} \overline{x_{\ell_3, m_1 + m_2, s_3}}$$

$$\times (-1)^{N_1 + N_2 + m_1 + m_2} \begin{pmatrix} \ell_1 & \ell_2 & \ell_3 \\ N_1 & N_2 & -N_1 - N_2 \end{pmatrix}$$

$$\times \begin{pmatrix} \ell_1 & \ell_2 & \ell_3 \\ m_1 & m_2 & -m_1 - m_2 \end{pmatrix}$$

$$\times \beta_{\ell_1, s_1; N_1, n_1} \beta_{\ell_2, s_2; N_2, n_2} \overline{\beta_{\ell_3, s_3; N_1 + N_2, n_3}}.$$

Combining Eq. (61) with Eq. (59) provides the explicit relation between the third-order autocorrelation and the volume.

Recall that we obtain the autocorrelations of the volume in PSWFs coefficients; see Eq. (53). Hence, to conclude the derivation we expand

$$\langle a_{I_{\omega}}^3[\ell_1, \ell_2] \rangle_{\omega} = \sum_{k, q_1, q_2} a_x^3[k, q_1, q_2] \psi_{k, q_1}[\ell_1] \overline{\psi_{k, q_2}[\ell_2]},$$

where we only include the block-diagonal terms in the expansion; the rest are equal to zero. Let

$$\Psi_{\ell, N, s}[\ell] := \sum_{n=0}^{n_{\max}(N)} \beta_{\ell, s; N, n} \psi_{N, n}[\ell],$$

$$\rho_{\ell, N, s}^{(k, q)} := \int_{\ell} \Psi_{\ell, N, s}([\mathbf{i} + \ell]) \overline{\psi_{k, q}(\ell)}.$$

Then, the final formula reads

$$a_x^3[k, q_1, q_2] = \sum_{\substack{\ell_1, m_1, s_1 \\ \ell_2, m_2, s_2 \\ s_3}}^{\min(L, \ell_1 + \ell_2)} \sum_{\ell_3 = |\ell_1 - \ell_2|} x_{\ell_1, m_1, s_1} x_{\ell_2, m_2, s_2} \overline{x_{\ell_3, m_1 + m_2, s_3}}$$

$$\times (-1)^{m_1 + m_2} \begin{pmatrix} \ell_1 & \ell_2 & \ell_3 \\ m_1 & m_2 & -m_1 - m_2 \end{pmatrix} \quad [62]$$

$$\times \sum_{N_1 = -\ell_1}^{\ell_1} \sum_{N_2 = -\ell_2}^{\ell_2} (-1)^{N_1 + N_2} \begin{pmatrix} \ell_1 & \ell_2 & \ell_3 \\ N_1 & N_2 & -N_1 - N_2 \end{pmatrix}$$

$$\times \frac{1}{L^2} \sum_{\mathbf{i}} \Psi_{\ell_1, N_1, s_1}[\mathbf{i}] \rho_{\ell_2, N_2, s_2}^{(k, q_1)}[\mathbf{i}] \overline{\rho_{\ell_3, N_1 + N_2, s_3}^{(k, q_2)}[\mathbf{i}]}.$$

In practice, the last two lines of the above expression for $a_x^3[k, q_1, q_2]$ is precomputed, and both the integration over \mathbf{i} and over ℓ is performed on the grid of the images in the dataset, to match the integration performed on the actual images.

Second-order autocorrelation. The second-order autocorrelation is easier to derive directly in Fourier space, to avoid integration of shifted PSWFs against centered ones. The relation between the second-order autocorrelation of the micrographs and the volume is given in Eq. (44) and Eq. (52). The connection with the expansion coefficients of the volume can be derived in Fourier space directly from Kam's original formula (10) by setting $\mathbf{k}_1 = \mathbf{k}_2$ to obtain

$$\langle a_{I_{\omega}}^2(k, \theta) \rangle_{\omega} = \frac{1}{4\pi} \sum_{\ell, m} \left| \sum_s x_{\ell, m, s} j_{\ell, s}(k) \right|^2$$

$$= \frac{1}{4\pi} \sum_{\substack{\ell, m \\ s_1, s_2}} x_{\ell, m, s_1} \overline{x_{\ell, m, s_2}} j_{\ell, s_1}(k) j_{\ell, s_2}(k),$$

where we used the fact that the normalized spherical Bessel functions $j_{\ell, s}$ are real.

As before, we want to derive the relation with respect to the PSWF coefficients of the autocorrelation. Hence, we expand the above in 2-D PSWFs by

$$\langle a_{I_{\omega}}^2(k, \theta) \rangle_{\omega} = \sum_q a_x^2(q) \psi_{0, q}(k),$$

and conclude that

$$a_x^2[q] = \frac{1}{\sqrt{8\pi}} \sum_{\substack{\ell, m \\ s_1, s_2}} x_{\ell, m, s_1} \overline{x_{\ell, m, s_2}} \int_0^1 j_{\ell, s_1}(k) j_{\ell, s_2}(k) R_{0, q}(k) k dk. \quad [63]$$

The integral on k is precomputed.

The mean. Since $j_{\ell, s}(0) = 0$ unless $\ell = 0$, and since $Y_{0,0}(\theta, \varphi) = \frac{1}{\sqrt{4\pi}}$, we conclude from Eq. (55) that

$$a_x^1 = \langle a_{I_{\omega}}^1 \rangle_{\omega} = \widehat{\phi}(\mathbf{0}) = \frac{1}{\sqrt{4\pi}} \sum_s x_{0,0,s} j_{0,s}(0). \quad [64]$$
